**Abstract:** Deep learning hardware accelerators based on analog photonic networks are trained on standard digital electronics. We discuss on-chip training of neural networks enabled by a silicon photonic architecture for parallel, efficient, and fast data operations. © 2022 The Author(s)

Driven by advances in integrated optics enabled by CMOS-compatible silicon photonics, the rise in artificial intelligence (AI) enabled by neural networks models, and programmable analog photonic integrated circuits, neuromorphic (neuron-inspired) photonic systems [1-3] have been proposed as accelerators for tensor cores for matrix multiplications [4-6], neuromorphic computing [7-11], and machine learning inference [12-14]. However, for the neural network to perform a practical task, the optimal network parameters (weights and biases) must first be determined using deep learning training algorithms. These algorithms have high computation and memory costs that challenge the current hardware platforms executing them [15]. The substantial energy required to train large neural networks using standard von Neumann architectures presents a high financial and environmental cost [16]. Training large neural networks is an area of machine learning that would benefit from photonics' low power consumption and high information processing bandwidth.

The recently proposed direct feedback alignment (DFA) supervised learning algorithm [17] has gathered interest as a bio-plausible alternative to the popular backpropagation training algorithm [18]. The DFA algorithm is a supervised learning algorithm that propagates the error through fixed random feedback connections directly from the output layer to the hidden layers during the backward pass [18]. Unlike backpropagation, the DFA algorithm does not require the network layers to be updated sequentially during the backward pass, enabling the algorithm to be a suitable candidate for efficient parallelization using photonics. The training algorithm has been used to train neural networks using the MNIST, CIFAR-10, and CIFAR-100 datasets and yields comparable performance to backpropagation [18]. The DFA algorithm has also been shown to perform fine-tuned backpropagation in applications requiring state-of-the-art deep learning networks, including natural language processing and neural view synthesis [19]. A recent theory suggests that training shallow networks with the DFA algorithm occurs in two steps: the first step is an alignment phase where the weights are modified to align the approximate gradient with the actual gradient of the loss function, which is followed by a memorization phase where the model focuses on fitting the data [20].

This talk will summarize our recently proposed silicon photonic architecture [21] that uses an electro-optic circuit to calculate the gradient vector of each neural network layer in situ, the most computationally expensive operation performed during the backward pass. The proposed architecture exploits the speed (10s of GHz range in photonics but only 100s of MHz in electronics) and energy advantages of photonics to determine the gradient vector of each neural network layer in a single operational cycle.

While practical neuromorphic processors may be years away, we have outlined in [2], [22] some scientific and technological advances necessary to meet the challenges.
